ABSTRACT

Recombination rates along wheat chromosomes can vary significantly. Recombination hotspots are common in the telomeric regions of the wheat chromosomes while largely void in centromeric regions. This has consequences for plant breeders who ideally would like maximum recombination among all genes in order to maximize variability. Disturbances in meiosis can lead to changes in the rate and distribution of chiasmata within paired homologues. In this thesis, the influence of alien chromatin on recombination in two tetraploid wheat backgrounds was examined. The material was developed from Langdon triticale (AABBRR; Langdon X Rye-13) and alien addition line DGE-1 along with two tetraploid (AABB) durum wheats, Langdon and W9262-260D₃. Three crosses were made in which the first cross was the normal durum wheat cross (Pop1; Langdon/W9262-260D3), the second was between the hexaploid triticale and durum wheat (Pop2; Langdon triticale/W9262-260D3) so that rye univalents would be present during the F₁ meiosis. The third was between an addition line and durum wheat named as Pop3 (DGE-1/W9262-260D3). For each F₂ population, the genetic mapping of extracted DNA samples was performed using genotypic data derived from the wheat 90K iSelect array and the recombination rates were estimated using MareyMap. The genetic maps from all of these crosses were compared with the map of the durum DH population (Kofa/W9262-260D3). Comparative analysis revealed the presence of alien chromatin both increased and suppressed recombination in the chromosomes. In Pop2 and Pop3, the telomeric regions showed maximum recombination in chromosomes 1A, 1B, 2A, 2B, 3A, 3B, 6A, 6B, and 7A. On the other hand, Pop2 showed suppressed recombination at some points in chromosome 2A, 2B, 3A, 5B, and 6A whereas in Pop3, in chromosomes 3A, 4B, 5A, and 7B, recombination was low at some points as compared to Pop1 and DH population. However, the maximum recombination occurred in the peri-centromeric and telomeric regions for both the populations with alien chromatin. Hence, the results showed the positive impact of alien chromatin on genetic recombination in the wheat homologous chromosomes and the presence of alien chromatin can be helpful in enhancing recombination rates in wheat which could be a useful breeding strategy.

This thesis is dedicated to my family.

ACKNOWLEDGEMENTS

It is my genuine pleasure to express my heartfelt thanks and gratitude to both of my supervisors, Drs. Graham Scoles and Curtis Pozniak, for their constant support throughout my master's program. Their intellectual advice, meticulous scrutiny, and scientific approach have always proved to be a great help. Their friendly attitude allowed me to talk my mind and heart out with them. I would also like to thank my advisory committee members, Dr. Kirstin Bett, Dr. Sateesh Kagale (National Research Council), and Dr. Tim Sharbel, as well as my external examiner Dr. for their time, insights and recommendations.

I would like to express my gratitude to the Saskatchewan Wheat Development Commission for funding this project. Many thanks to durum wheat lab members for providing all the training and academic support during my research. A special thanks goes to Dr. Amidou N'Diaye for helping me in genetic mapping and recombination studies, Jennifer Ens, Krysta Wiebe, Justin Coulson, and Lexie Martin for helping me in DNA extractions and genotyping, and also Vinh Tang and Heidi Lazorko for teaching me the crossings in wheat. I would also like to acknowledge Global Institute for Food Security for conducting flow cytometry experiments related to my thesis. A sincere thanks to Ann Harley, the entire Plant Sciences (PLSC) staff, faculty and students to make me feel like home away from my family. I really appreciate their friendliness and kindness that have moved the hearts of many.

I would like to express special thanks to the almighty and to my family (my loving grandparents, my biggest support my father, my mother and my brother) for inspiring and giving me strength to face every challenge in life with positivity. I could not have come this far without their presence in my life. And of course, my roommates who played an important role with being available in all my ups and downs.

1.0 INTRODUCTION

1.1 Background

Genetic diversity is the basis for crop improvement, and germplasm diversity plays a significant role in the improvement of crop plants (Huang *et al.*, 2002). Plant breeders often intercross among elite materials when developing new cultivars, but this results in a narrow genetic base and can slow genetic gains (Lambing *et al.*, 2017). To broaden the genetic variation in wheat breeding, one strategy is to utilize the genetic diversity available in the secondary and tertiary genepools of wheat (Huang *et al.*, 2002).

Wheat is one of the oldest and most important cereal crops. It is the staple crop in various developing countries and its consumption is increasing globally. Bread wheat (*Triticum aestivum* L. em Thell) and durum wheat (*Triticum turgidum* spp. *durum*) are the two major wheat species grown throughout the world (Shewry and Hey, 2015), and were domesticated approximately 10,000 years ago. The first allopolyploidization event resulted in the extant tetraploid emmer wheat (AABB, $2n=4x=28$) which involved the A subgenome from *Triticum urartu*, and the B subgenome from an unknown relative of *Aegilops speltoides* (Marcussen *et al.*, 2014). This tetraploid wheat was then hybridized with the D subgenome from *Aegilops tauschii* to form modern bread wheat with the hexaploid genome (AABBDD, $2n=6x=42$ chromosomes) (Marcussen *et al.*, 2014). Hence, polyploidization and domestication initially, and more recently modern plant breeding, has resulted in a narrow genetic base (Dubcovsky and Dvorak, 2007; Charmet, 2011). Domestication and farmer selections gave rise to landraces adapted to the local climate. This marked the start of a reduction in genetic variation through genetic drift and selection (Smale *et al.*, 2005). Hence, most grain crops are facing the problem of a narrow genetic base which limits their potential for adaptation to climate change and resistance to biotic and abiotic stresses. The wild relatives of wheat are an abundant source of agronomically important traits as resistance to biotic stress (fungal diseases and insect attack)/abiotic stress (heat, drought, and salinity), known for wider adaptation and plant production as photosynthetic capacity, quality, yield and for the development of new crop species and varieties (Reif *et al.*, 2005). However, utilization of wild relatives in breeding is often associated with linkage drag resulting in deleterious traits that limit the gain of useful alleles (Mondal *et al.*, 2016; Gardiner *et al.*, 2019). Linkage drag is challenging to break especially in the regions of chromosome with

low recombination (Wulff and Moscou, 2014). Hence, strategies to promote recombination can be helpful in breaking up undesirable linkage blocks to introduce desirable genes (Gardiner *et al.*, 2019).

Recombination is a fundamental biological process which includes reshuffling of genetic information which leads to the production of new haplotypes and hence, an evolutionary requirement to incorporate genetic diversity across a species (Jordan *et al.*, 2018).

Recombination, being an important part of meiosis, can help in breaking linkage among the alleles that have either deleterious or beneficial effects in the genetic background and also helps in enhancing the response to selection by increasing genetic variability (Hill and Robertson, 1966; Comeron *et al.*, 2008). Various strategies have been pursued to modulate the recombination frequency along the length of chromosomes especially in the peri-centromeric regions. These strategies include the use of knock-out mutants of anti-crossover genes, crosses among different ploidy levels, clustered regularly interspaced short palindromic repeat (CRISPR)/CRISPR-associated protein 9 (Cas9) mediated gene targeting, and abiotic and biotic treatments to alter recombination (Tourrette *et al.*, 2019, Huang and Puchta, 2019, Lambing *et al.*, 2017). Intercrossing species with varying ploidy levels results in the introduction of univalents in the genome which activate meiotic checkpoints promoting an extended active recombination state with a resulting improvement in the crossover (CO) number and their distribution. This can result in changing recombination along the length of chromosomes especially in the peri-centromeric regions (Suay *et al.*, 2014). Hence, to facilitate sustainable wheat production and quality along with future selection gain, recombination can be used for the modification of genome-wide gene networks by making new crosses in order to control expression of various complex traits (IWGSC, 2018).

1.2 Project hypotheses

1. Distribution of COs and recombination is uneven along durum wheat chromosome pairs.
2. The presence of unpaired univalents at meiosis will affect the distribution of COs among wheat chromosome pairs, and hence recombination between paired chromosomes, and be evident by differences between the F₂ linkage map of two durum parents and the maps produced when univalents are present at the F₁ meiosis.

1.3 Project Objectives

1. To estimate the recombination rates of durum chromosomes for Kofa/W9262-260D3 population to check the difference in recombination rates.
2. To develop genetic maps of three populations (wheat x wheat, wheat x triticale with seven univalents at the F₁ meiosis and wheat x an addition line with one univalent at the F₁ meiosis).
3. To compare the recombination rates, CO distribution and/or frequency among linkage groups of the three populations to determine whether they were affected by the presence of univalents at meiosis.

2.0 LITERATURE REVIEW

2.1 Wheat: production and importance in Canada and worldwide

Wheat (*Triticum* spp.) is a monocotyledonous plant, a member of the Poaceae family and widely cultivated for its grain. The Fertile Crescent region around the Tigris and Euphrates rivers is known to be the center of origin of wheat (Campbell, 2013; Marcussen *et al.*, 2014). Wheat is one of the most important food grain sources for humans and has been the primary food for 10,000 years in Europe, Southwest Asia and North Africa (Curtis and Halford, 2014) and was introduced to North America in the late 15th and 16th century (Campbell, 2013). Wheat evolved from natural crossings of wild species and was domesticated further by humans. Common wheat (*Triticum aestivum* L. em Thell) and durum wheat (*Triticum turgidum* spp. *durum*) are the most important crops grown around the world (Marcussen *et al.*, 2014). In Canada, spring-habit types are preferred by growers, with winter types accounting for only five percent of wheat production. The minimum and maximum temperature, required for wheat growth, are 3° to 4°C and 30° to 32°C, respectively, but the optimum temperature is 25°C (Curtis and Halford, 2014).

In Canada, Port-Royal (near Annapolis Royal, Nova Scotia) was the first place where wheat was grown in 1605 (Campbell, 2013). Canada is the sixth-largest producer of wheat with an average of over 25 million tonnes and exporting around 15 million tonnes. Saskatchewan, followed by Alberta and Manitoba are the largest producers of wheat in Canada (Campbell, 2013). For 2019-20 Canadian durum production decreased by 13% from 2018-19 to 4.98 million tonnes (Mt). Saskatchewan produced 86.5%, followed by Alberta and Manitoba with 13% and 0.5% production, respectively. Excluding durum, wheat production increased by 3.5% from 2018-19 to 27.4 Mt. Saskatchewan produces 39.5% of Canada's wheat. Alberta, Manitoba, Ontario, and Quebec accounted for 35%, 18%, 5.5%, and 1% of the wheat production, respectively. The remaining 1% was from the Maritimes and British Columbia (Anonymous, 2019a).

Wheat has high economic importance as it contributes to the human diet as a staple food for millions of people worldwide and also animal feed (Curtis and Halford, 2014). It provides 327 calories (per 100 grams) and is also a rich source of protein, fiber, manganese, phosphorus, and niacin. The wheat caryopsis consists of 13% water, 13% protein (75-80% gluten), 71% carbohydrates and 1.5% fat. It contributes about one-fifth of the calories consumed by humans, including nutritional factors, bioactive phytochemicals namely, phenolic acids, carotenoids,

tocopherols, alkylresorcinols, benzoxazinoids, phytosterols, and lignans as well as the dietary fiber component (Shewry and Hey, 2015). Wheat is easy to store. It can be easily converted from grain to flour and is a major ingredient in bread, biscuits, pancakes, pies, pastries, cakes, cookies, doughnuts, noodles, pasta as well as instant breakfast cereals (Shewry and Hey, 2015).

2.2 Meiosis and recombination

Meiosis is a significant and specialized process of cell division that gives rise to the formation of gametes with half the chromosome number, thereby allowing the restoration of the ploidy level during fertilization (Lambing *et al.*, 2017). In most of the eukaryotes, this phenomenon is conserved (Mercier *et al.*, 2015). It consists of two types of divisions, a reductional and an equational division respectively. The first division includes the pairing of homologous chromosomes as well as their subsequent segregation and the second division is similar to mitosis in which the segregation of sister chromatids take place. Recombination occurs during prophase-I which is the longest and very important phase of meiosis. During recombination, the homologous chromosome pairs form tetrads. Within the tetrad, chromatid arms of paired chromosomes can overlap and fuse which is called crossing over (CO) (Mercier *et al.*, 2015; Schwarzacher, 2003). Cytologically, the COs between homologues are manifested in the form of chiasmata. A CO is formed as a result of the recombinational repairing process of a section of DNA double-strand breaks (DSB). At the start of meiotic prophase-I, topoisomerase-like SPO11 protein gives rise to DSB. These CO sites are the regions where two homologous non-sister chromatids exchange genetic information (Keeney *et al.*, 1997). CO serves an important function of protecting physical connections between homologous chromosomes which is helpful in their co-orientation and proper disjunction at meiosis-I. However, the number of COs is tightly controlled as too many or too few COs are disadvantageous (Jones and Franklin, 2006). Two aspects are responsible for CO control, namely, obligate CO and CO interference. At least one CO per chromosome pair exists to assure the correct segregation of homologues. This “obligate” CO is important for the balanced distribution of chromosomes among the gametes (Jones, 1984). Typically, one to three COs can occur between homologous chromosomes regardless of chromosome size. It is very rare to find chromosomes that do not undergo CO. Interference also affects the position of CO, the formation of a CO in one region limits the probability that a second CO can occur simultaneously in an adjacent region (Muller, 1916; Sturtevant, 1915). COs

are not evenly distributed along the length of chromosome (Lukaszewski and Curtis, 1992). However, the number of DSBs is found to be at least 10-50 fold greater than the number of COs and the number of COs rarely exceed three for each bivalent chromosome per meiosis (Mercier *et al.*, 2015). Distribution of recombination/COs is significantly different in physically short and long arms of chromosomes. In short arms, the recombination events are more concentrated to the distal segments whereas in long arms, both distal and interstitial recombination was observed (Maccaferri *et al.*, 2019). This recombination pattern was found to be a result of telomeric pairing initiation as well as due to strong positive chiasma interference (Lukaszewski and Curtis, 1992). Hence, recombination includes the points of exchange of genetic material between a pair of homologous chromosomes. The random disjunction and recombination of parental chromosomes (and genes) gives rise to new and different allelic combinations and hence contributes to genetic variability (Schwarzacher, 2003). This gene reshuffling is essential in a breeding program for crop improvement.

2.3 Measuring recombination rates

Genotyping determines the genetic variants possessed by an individual by studying their DNA sequence. Genotyping reveals the alleles of an individual at defined loci in the genome. Depending on the variants of interest and availability of resources, there are various methods to perform genotyping (Anonymous, 2019b). High density single nucleotide polymorphism (SNP) genotyping arrays are widely used for studying genome-wide patterns of genetic variation and can be helpful in identifying putative targets of selection by dissecting complex traits in the wheat genome (Cavanagh *et al.*, 2013; Wang *et al.*, 2014). As SNPs are a ubiquitous kind of genetic variation, they are ideally used for the construction of high-resolution genetic maps and to discover marker-trait association in quantitative trait locus (QTL) mapping experiments (Akhunov *et al.*, 2009). The wheat iSelect array, comprising of 81,687 gene-associated SNPs, was developed for the dense coverage of the wheat genome using eight mapping populations. Out of those, 46,977 SNP markers were mapped genetically and create a resource for studying genome-wide variation and haplotype structure in allohexaploid and allotetraploid wheat populations (Wang *et al.*, 2014) and for establishment of wheat consensus linkage maps (Wang *et al.*, 2014; Maccaferri *et al.*, 2015). In order to achieve high quality genotype calling, density-based spatial clustering algorithms were used because in polyploids the ratio of allelic variants

show deviation from the ratio in diploid organisms, and interference of paralogous loci and secondary SNPs with genotyping oligonucleotide annealing which makes genotype clusters formed as a result difficult to analyse (Akhunov *et al.*, 2009; Wang *et al.*, 2014). In the presence of multiple clusters, these algorithms provide high quality genotype calling and even show low intensity signal in case of presence-absence variations (PAVs) and sequence divergence of SNP assay probe hybridization sites. Hence, SNP based platforms are very useful as these are easy to use with reduced computational data processing, high quality genotype call frequency, and a low error rate (Wang *et al.*, 2014). The classical approach used for the estimation of recombination rates is to build a high-density genetic linkage map and then match these maps to the corresponding physical maps which can help in measuring recombination rate from genetic distance divided by physical distance (Gion *et al.*, 2016). Hence, the wheat 90K iSelect array is helpful in generating high-density genetic maps for analysing genome-wide variations in wheat as these assays provide information related to the structural organization of the wheat genome unfolding old and newly characterized rearrangements between homoeologous chromosomes (Wang *et al.*, 2014).

2.4 Meiosis and crossover distribution in wheat

At meiosis, both hexaploid and tetraploid wheats show regular pairing at metaphase-I and behave as diploids. The homologous chromosomes of wheat strictly form bivalents ignoring their genetic similarity with homoeologues and show a disomic inheritance (Sears, 1976). The *Ph1* locus, present on the long arm of 5B chromosome, has a major dominant effect on the diploid-like meiotic behavior of wheat (Riley and Chapman, 1958). Previous studies in wheat revealed that recombination increases gradually from centromere to telomere and preferably occurs in the telomeric regions of chromosomes (Lukaszewski and Curtis, 1992; Erayman *et al.* 2004). Saintenac *et al.* (2009) also showed that the frequency of CO occurrence (recombination) is higher in sub-telomeric regions and lower in interstitial regions. They studied the pattern of CO along chromosome 3B of bread wheat. Almost 90% of COs occurred in the distal (subtelomeric) region, about 40% of the chromosome. A very low CO frequency was recorded in the proximal regions surrounding the centromere, about 27% of the chromosome (Saintenac *et al.*, 2009). The fully assembled genome of the modern durum wheat cultivar (cv.) Svevo gave genome-wide information of recombination (Maccaferri *et al.*, 2019). Alignment of this genome with high-

density SNP genetic maps revealed highly recombinogenic distal regions showing a linear relationship between genetic and physical distance and these distal regions showed an average recombination rate of 1.8 Mb cM^{-1} which was about 22% of the genome (Maccaferri *et al.*, 2019). Whereas the peri-centromeric regions were found to be devoid of recombination covering about 44% of the genome (Maccaferri *et al.*, 2019). Hence, distal regions of chromosomes are the preferential targets of meiotic recombination and are known to be the fastest evolving (IWGSC, 2018). The International Wheat Genome Sequencing Consortium (IWGSC) released annotated and ordered reference genome sequence of the wheat landrace “Chinese Spring”, which provides insights into the distribution of meiotic recombination frequency and genomic diversity which can be helpful in strategies to bring desirable alleles which lie especially in less-recombinant regions of the wheat genome (IWGSC, 2018).

2.5 Manipulating crossover distribution

It has been demonstrated that the CO frequency can be manipulated experimentally in a chromosome segment (Jones *et al.*, 2002). The genetic mapping in normal, deletion (Del1B45L) and deficiency (Df1B23L) chromosome arms 1BL of hexaploid wheat cv ‘Chinese Spring’ was performed to check the overall pairing and recombination frequencies. The development of genetic linkage maps of chromosome constructs was done using eight markers including the *Glu-B1* locus, the centromere and six microsatellite markers: *Xgwm124*, *Xgwm131*, *Xgwm140*, *Xgwm259*, *Xgwm268*, and *Xpr3100*. The pairing between the normal arms was in the range of 90 to 95% and observed that the total genetic length has an average of about 1.6 CO per arm. Normal chromosome arm 1BL and Del1B45L (deleting the proximal 45% of the arm) were structurally similar in the terminal regions and their Meiosis I-pairing was normal. It was found that pairing of Del1B45L with the normal 1BL arm showed no significant effect but the average number of COs per arm was significantly reduced to 1.2 CO. Also, the maps of the complete and deletion chromosomes showed similar distribution of the distal markers. In the deficiency chromosome, missing the terminal 23% of the normal arm makes direct monitoring of recombination impossible in most of the arm because of the removal of five distal markers. The recombination frequency was estimated by its MI pairing frequency. In the terminal segment of the deficiency chromosome, the recombination rate was found to be much higher than that in the same segment of the pairing of complete arm. This shows that recombination frequency of a

segment depends on its position on the centromere-telomere axis. Hence, they concluded that shortening of the chromosome decreased the frequency of multiple CO significantly in the proximal regions of the chromosome but did not affect the distal CO distribution, presumably the first CO in the arm.

In cereals, COs are predominantly positioned towards the distal regions of the chromosome (Saintenac *et al.*, 2009). In barley, Higgins *et al.* (2012) investigated some factors which contribute to the pattern of recombination in barley. They revealed that the pattern of events, including the initiation and progression of meiosis, chromosome axis formation, and synapsis, is connected to the relative timing of DNA replication for heterochromatin and euchromatin-rich DNA. Early recombination initiation is spatially linked with euchromatic DNA which is early replicating and can be found mostly in distal regions. Higgins *et al.* (2012) found that a change in temperature from 22°C to 30°C resulted in an increase in interstitial and proximal chiasmata. There was no change in the duration of meiosis (~43 h at both 22 and 30°C), but this temperature shift is responsible for disturbing S-phase, which results in a disruption of meiotic control and causes early replication of heterochromatin-rich DNA followed by a change in the frequency and distribution of chiasmata. At the distal regions, the replication was completed in 0-4 hour at both temperatures (22 and 30°C) without any effect and there was no apparent change in euchromatin abundance, but at 30°C, the interstitial and proximal heterochromatic regions showed fast replication and subsequently, enter meiosis early. They observed a significant increase in interstitial/proximal chiasmata as 0.58 to 1.13 chiasmata per cell. Higgins *et al.* (2012) suggested this could be a potential way to change recombination in cereals.

In barley, work done by Phillips *et al.* (2015) tested whether the effect of CO can be shifted to more proximal regions just by elevating growth temperature and can help in increasing overall recombination frequency. Heterochiasmy, that is, difference of recombination rates between male and female and elevated growth temperature are the two important factors in the control of recombination in which male and female meiosis show different CO frequencies and distribution. The significant differences were found between male and female recombination frequencies by performing reciprocal crosses. At 15°C, the CO frequencies showed a slight elevation in male meiosis as compared to the female with a ratio of 1.05, but the difference was not that significant. At 25 and 30°C, CO frequencies in the male showed an incremental rise,

with ratios of 1.20 and 1.58, respectively. However, there was a fall in female CO frequencies with increasing temperature. They suspected that an increase in CO frequency in male meiosis might be associated with an increase in the average single CO length of the bivalents in response to temperature. Also, as suggested by Higgins *et al.* (2012), genes, responsible for controlling the cell cycle and chromatin state as in pre-meiotic and early meiotic stages, are also involved in changing the CO frequencies and distribution under different rising temperatures.

Si *et al.* (2015) performed fine-scale mapping of CO in rice and revealed that genes present in recombination hotspots were involved in responses to environmental stimuli. To confirm this, some F₁ plants were grown in normal growth conditions, whereas others were treated with abiotic or biotic stresses (pathogen attack using rice blast spores), drought, UV-B radiation, high (38°C day/32°C night) and low (20°C day/10°C night) temperature during the period of meiosis, at least 10 days before the booting stage and continued until the maturation of the seeds. Hundreds of F₂ seeds were harvested from these F₁ plants and grown under the same normal growth conditions. The CO events were counted in 41 rice individuals (including normal and stressed F₂ plants along with their normal F₁ parents) mapped using 900,000 markers. They found that COs were distributed unevenly among and along the chromosomes. The average number of CO events (35.8, ranging from 24 to 52) per meiosis in stressed individuals was slightly larger than that of normal individuals (32.8 ranging from 23 to 42). On the basis of the distribution of meiotic CO events along the chromosomes, there were 13 cold spot regions, marked ~13.9% of the rice genome, without even a single CO event. Out of these, 11 regions were found on centromeres and peri-centromeric regions. About 27 regions, defined as hot spots, were detected with extremely high recombination rates and were about 0.72% of the genome with approximately 9.1% CO events clustered within a few hundreds or thousands of base pairs. Hence, frequent recombination has a vital role in the adaptive evolution of the plants surviving in the frequently changing environment (Si *et al.*, 2015).

Genomic structure is also responsible for regulating the frequency and placement of CO. During meiosis, homologous chromosomes undergo recombination. Ziolkowski *et al.* (2015) found that sequence differences between homologs are responsible for inhibiting the nearby CO. In Arabidopsis, lines carrying fluorescent CO reporters were crossed with 32 diverse accessions to find the relation between heterozygosity and recombination. By studying the recombinant progenies, they observed that there was an increase in CO in heterozygous regions when there

were homozygous regions in its proximity. Whereas, they found a decrease in the number of CO in the homozygous areas. The increased number of COs in the heterozygous areas was thought to cause an increase in the strength of CO interference which results in preventing COs from occurring in the adjacent homozygous regions. The balance of interfering and non-interfering CO repair was altered in hybrids due to heterozygosity. They found that at homozygosity-heterozygosity junctions, the non-interfering repair was inefficient. Due to this, higher levels of CO interference were reported in heterozygous regions and this interference is responsible for the change in the CO pattern across the homozygosity-heterozygosity junctions. In conclusion, the variation in homolog polymorphism patterns could control the meiotic recombination (Ziolkowski *et al.*, 2015).

In *Caenorhabditis elegans*, Carlton *et al.* (2006) showed that the presence of a single pair of univalents during meiosis is responsible for inducing an increase in COs in the remaining bivalents. The presence of unsynapsed chromosomes resulted in delaying normal progression of meiotic nuclear reorganization from early to late pachytene. Nuclei that linger in early pachytene, containing unsynapsed chromosomes, have more chances for exchange to occur. This exchange can either happen through the beginning of new recombination events or by the conversion of existing recombination intermediates into COs and hence increase the CO recombination on the normally synapsed chromosomes (Carlton *et al.*, 2006).

Andronic (2012) performed some experiments to prove that plant viruses can trigger DNA re-arrangements in host plants and to induce genetic variability in susceptible hosts. Assessment of microsporogenesis was done in tomato infected with tomato aspermy virus and barley infected with barley stripe mosaic virus. Viral infection leads to deviations in the conjugation (pairing) of homologous chromosomes, segregation of genetic material and changes in the position and number of terminal and interstitial chiasmata. Chromosomal aberrations and the mean percentage of abnormal pollen mother cells used in the cytogenetic evaluation of microsporogenesis revealed significant changes in the chiasmata position and number. In some viral treatments, new synaptic cohesions were observed, as there was an increase in bivalents with one or two interstitial chiasmata. The critical observation was that the chromosomal figures in diakinesis showed some synaptic cohesion with chiasma formation or failure/losses of conjugation, giving rise to univalents and considered as an interchromosomal effect in regulating the meiotic recombination. The univalent induction was deemed to be caused by asynapsis or

desynapsis. In asynapsis, the failure of conjugation between homologous chromosomes caused the synaptic arrest whereas in desynapsis, the primary cohesion was there, but disassembly of the synaptonemal complex was seen at diplotene-diakinesis, giving unsynapsed chromosomes. In desynapsis, at diakinesis, chromosomal figures showed synaptic cohesion and chiasma formation or conjugation failures, forming univalents. It was observed that viral infection has an impact on the meiotic conjugation and its abnormality can cause the deviation in the following mitotic stages and can further reduce the number of normal microsporocytes.

Suay *et al.* (2014) studied the CO rate between homologous chromosomes in the presence of univalents and found their effect on the regulation of interference in canola by comparing genetic map lengths. They found that in *Brassica napus* (AACC, 2n=38), homologous recombination can be increased between A genome chromosomes in the presence of C univalents in AAC hybrids. Various factors are responsible for regulating the frequency of COs on the recombining chromosomes. Firstly, the number of C genome univalents present significantly affects the CO frequency as the map lengths (and recombination rates) were found to be more when the number of univalents was greater. Secondly, the ratio of the number of univalents and bivalents to each other also regulates the CO frequency. The recombination rate was higher for each pair of hybrids with 2n=32 (13II + 6I) or 2n=35 (16II + 3I) chromosomes. Concerning the map size of the A7 linkage group, it was significantly larger in the progeny of the 16II + 3I hybrid than the 13II + 6I hybrid. From the number of recombinant intervals per chromatid, it was found that the hybrids carrying more bivalents had more COs than the hybrids carrying fewer bivalents. Furthermore, the identity of univalent affects the triploid hybrid *B. napus* (AAC) by showing a significant increase in the recombination between A genome chromosomes in AA hybrids carrying specific univalents. The presence of one chromosome C-9 showed a reduction in CO interference and hence, significantly affects the recombination rate. The recombination rates were 1.4 times higher in the hybrids having C-6 and 2.7 times higher in C-9 than in the control (0C). The rates showed further increase to 3.1 and 4.1 times in hybrids having only C-6 and C-9, respectively (Suay *et al.*, 2014).

Various attempts have been made and are in progress to introgress important traits from wild relatives into wheat. In interspecific hybrids, COs do not take place between homoeologous chromosomes during meiosis (observations made at metaphase I) due to the presence of *phl* locus. However, this problem can be solved by the use of mutant lines. Recently, Rey *et al.*

(2017) found that in chemically induced mutant lines, the *ZIP4* homologue within *Ph1* locus (*Tazip4-B2*), can be more useful than mutants with whole *Ph1* locus deletions. As these mutant lines on crossing with wild relatives, showed high levels of homoeologous COs and may be more stable over multiple generations because of lower multivalent formation which will lead to fewer chromosome translocations (Rey *et al.*, 2017). Li *et al* (2019) demonstrated a strategy to modulate recombination by targeting a specific alien chromosome with a specific wheat chromosome. The evidence showed that the introgression of *Su1-Ph1*, a suppressor of the *Ph1* gene of wheat, from *Aegilops speltoides* into durum wheat cv. Langdon enhanced the level of recombination between alien and wheat chromosomes. The Langdon plants targeted for recombination were heterozygous for *Su1-Ph1* containing a single Langdon chromosome 5B and a single *Aegilops searsii* chromosome 5S^{se}. The wheat 90K Illumina SNP assay was used for the genotyping of 28 BC₁F₁ and 84 F₂ progenies. In homoeologous maps, overall recombination was low with recombination being nearly absent in the short arm. The expected recombination rate estimated from 5B and 5S^{se} meiotic pairing was doubled but was depressed in the proximal regions of the long arm in comparison to that between 5B chromosomes. In wheat and its diploid relatives, distal regions are the preferential regions of recombination between homologues and recombination declines from distal to proximal direction. In comparison to this, recombination between 5B and 5S^{se} chromosomes was low but there was a slow increase in recombination in the proximal region of the long arm. Rare recombination events like more COs were seen in the proximal regions and low recombination regions including proximally located *Ph1* region (Li *et al.*, 2019). CRISPR/Cas9-mediated gene targeting is also utilized in introducing desired modifications within a target locus to improve the recombination by inducing double-strand breaks using site specific nucleases (Huang and Puchta, 2019). Recently, in Drosophila, it was found that CRISPR-induced double-strand breaks can be helpful in triggering recombination between homologous chromosome arms up to 39% (Brunner *et al.*, 2019). However, it was also revealed that precise editing is helpful in specifically editing the locus as instructed by provided endogenous or exogenous template and on the other hand, imprecise double-strand repair may lead to random mutations (Brunner *et al.*, 2019). IWGSC RefSeq v1.0 could speed up the diagnostic marker development and designing of targets using CRISPR-Cas9-based gene editing as this technique has also been used for controlling the flowering genes by refining the annotations of their sequences which helped in identifying high-confidence genes and designing

of guide RNAs to target the specific genes (IWGSC, 2018). IWGSC RefSeq v1.0 unfolds the wheat genome by providing access to regulatory regions, and QTLs. This knowledge along with genomic diversity and distribution of meiotic recombination can help breeders to potentially overcome the challenges for the crop improvement by accessing genes lying in low-recombination regions of the wheat genome (IWGSC, 2018).

3.0 MATERIAL AND METHODS

3.1 Plant material

1. The DH mapping population derived from the cross Kofa/W9262-260D3, was used for this study. This population was used extensively by Nilsen *et al.* (2017) for the study of the major stem-solidness locus *SSt1* in durum. Kofa is a hollow-stemmed cultivar from the United States whereas W9262-260D3 is derived from the cross Kyle*2/Biodur and is a solid-stemmed cultivar (Houshmand *et al.*, 2007).
2. The plant material used for the second hypothesis included the durum wheat lines Langdon, and W9262-260D3, obtained from the CDC (Saskatoon), the synthetic amphiploid Langdon/Rye-13 (named as Langdon triticale hereafter) obtained from Agriculture and Agri-Food Canada - Ottawa Research and Development Centre (ORDC), and the disomic addition line DGE-1 ($2n= 28+2$), tetraploid wheat Langdon with a wheat grass (*Lophopyron elongatum* L.) chromosome pair, obtained from United States Department of Agriculture (USDA), Fargo, USA.

Crosses are shown in Fig. 3. The first cross was between two durum wheat parents, Langdon and W9262-260D3 (Fig. 3.1(a)). In the second cross, the tetraploid wheat W9262-260D3 was used as female and Langdon triticale was used as a male (Fig. 3.1(b)). The third cross was done in which the addition line DGE-1 was crossed with tetraploid wheat W9262-260D3 (Fig. 3.1(c))). Langdon is the common durum parent in all the crosses and the normal cross between durum parents was used as a reference to compare the recombination rates with other populations.

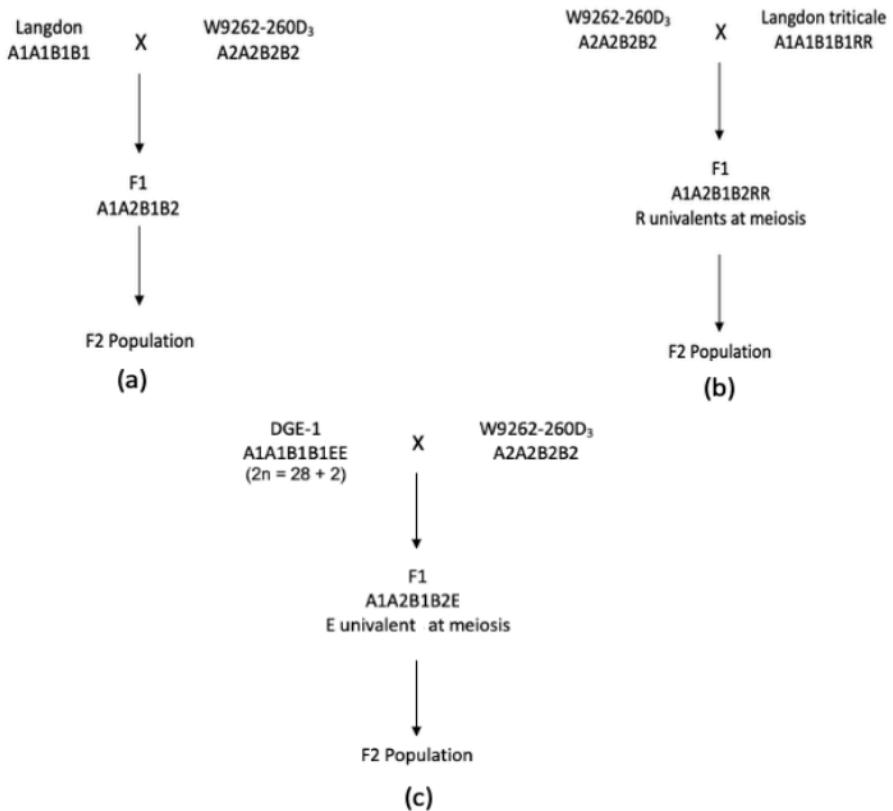

Fig. 3.1 Schematic representation of the production of hybrids. (a) Normal genetic mapping of crossed tetraploid wheat parents. (b) Genetic mapping of the cross between W9262-260D3 and DH (Langdon/Rye-13). (c) Genetic mapping of the cross between DGE-1 (addition line) and tetraploid wheat carrying E univalent.

3.2 Genotyping

The DNA was extracted from 155 durum DH lines of cross (Kofa/W9262-260D3) using a modified CTAB approach (CIMMYT, 2005). Agarose gels were used to check the DNA quality. DNA was diluted to 50 ng μL^{-1} and genotyping was done using the wheat 90K array (Nilsen *et al.* 2017). For the three cross populations, F₁ seeds were sown in pots (8" x 7" – 150 x 180 mm) and kept at 4°C for 24 hours in the growth chamber then shifted to the normal growth conditions 16 hours day, and 23/17°C day/night temperature in growth chambers. The DNA was extracted from the F₁s and parents at the seedling stage (2-3 leaf stage; Zadoks growth stage- Z12, Z13) using a modified CTAB method (CIMMYT, 2005) and KASP analysis using a gene specific marker of *Cdu1*, a gene responsible for controlling grain cadmium accumulation in tetraploid wheat (Wiebe *et al.*, 2010). This was performed to confirm and advance only those F₁ plants that

were true hybrids. For KASP analysis, a reaction plate was made by dispensing the genotyping mix, including DNA (1.2 µl), water (2.69 µl), primers (0.11 µl) (listed in Wiebe et al., 2010) and the SNP-specific KASP assay (4 µl), in the plate (Anonymous, 2014). A thermal cycling reaction was then performed with the following PCR conditions: hot start activation at 94 °C for 15 min, followed by 10 touch down cycles as 94 °C for 20 sec; touch down at 61-55 °C for 60 sec initially and dropping by 0.6-1 °C per cycle for 25 sec, and then followed by 26 more cycles of annealing as 94 °C for 20 sec; 55 °C for 60 sec (Anonymous, 2014). Each DNA sample represented individual data point. The KASP results were analyzed by viewing the fluorescence values of these data points in the form of cluster plots. Same genotype samples produced similar levels of fluorescence and hence clustered together (Anonymous, 2014). The F₁ plants confirmed to be true hybrids were then grown to maturity and F₂ grain from all the plants was harvested for further germination and DNA extraction.

Two hundred F₂ seeds from the crosses were grown, and DNA extraction was made from fresh leaves as described by modified CTAB approach (CIMMYT, 2005). To determine the concentration and quality of DNA, the samples were checked by electrophoresis on 2.0-2.5% agarose gels at 140V for 1.5 hours in 1X TBE buffer and stained with ethidium bromide (0.5 µg/ml) and diluted to 50 ng µl⁻¹, using lambda DNA as a standard. The DNA banding patterns were visualized with UV light and recorded by a Canon Power Shot 7 digital camera and UVP imaging system.

The wheat 90k iSelect assay was used for genotyping all the three populations along with their parents (Wang *et al.*, 2014). The clustering and genotype calling of SNP alleles was performed in Genome Studio (Illumina Inc., San Diego, CA, USA). The clustering includes identifying the assays which were producing three distinct clusters referring to the AA (homozygous with A allele), AB (heterozygous) and BB (homozygous with B allele) genotypes for biallelic SNPs. The sorting of parents was random including all probable cases. The construction of linkage maps was then done by filtering the SNPs on the basis of polymorphism between parents and missing data (>25%).

3.3 Construction of genetic linkage maps

The genotypic data of mapping population was filtered for the polymorphic markers. The distortion of molecular markers was tested using Chi-square (χ^2) test.

1. For Kofa/W9262-260D3, the markers with expected 1:1 ratio for DH populations were kept using a chi-square (χ^2) test. Markers showing significant segregation distortion (deviation from 1:1 ratio) were removed.
2. For the remaining three populations, markers showing significant segregation distortion from the expected chi-square ratio 1:2:1, 3:1, and 1:3 for F₂ populations were removed.

The MSTMap software (Wu et al., 2008) was used for generating draft maps with a *p*-value of 1e⁻¹⁰. MapDisto v1.7.5 software (Lorieux, 2012) was used further for refining of the maps using a threshold LOD score of 3.0. For grouping SNPs into linkage groups, the maximum distance between the markers was kept at 15cM for Kofa/W9262-260D3 population (Nilsen *et al.*, 2017) whereas for other three populations, the maximum distance was 30.0 cM and was calculated using Kosambi function. The linkage groups (LGs) were refined using “AutoCheckInversions”, “AutoOrder”, and “AutoRipple” to find the best order and also scanned as well as corrected for double recombinants. The marker positions were confirmed, and chromosomes were assigned to LGs using the high density 90K wheat consensus maps (Maccaferri *et al.*, 2014; Wang *et al.*, 2014).

3.4 Estimation of recombination rates

The physical position of each marker was determined by mapping the iSelect probe sequence to the Svevo durum wheat genome assembly (Macafferri *et al.* 2019). Both physical positions and genetic positions were used for estimating the local recombination rates along each chromosome using MareyMap (Rezvoy *et al.*, 2007). Scatter plots for each LG were generated to compare genetic (cM) versus physical position (Mb) in each cross population. The recombination rate at any given position was estimated by the slope of the curve in relation to genetic and physical maps. Recombination was analysed in non-overlapping 1 Mb windows with the ‘Loess’ method using MareyMap (Rezvoy *et al.*, 2007).

3.5 Statistical analyses

Data were analysed for each chromosome in Statistical Analysis Software (SAS) ver. 9.4. (SAS Institute Inc., Cary, NC). Mean comparisons of recombination rates were performed for each linkage group per chromosome using Fisher’s protected least significant difference (LSD) procedure to protect against Type-II error. For the Kofa/W9262-260D3 population, the mean comparisons among all durum chromosomes were used as a reference for comparative analysis

with the remaining two populations. The comparison between A and B sub-genomes was also performed to estimate the difference in recombination rates across the sub-genomes of wheat. The mean comparisons for the F₂ populations was in all combinations as well as with Kofa/W9262-260D3 population to analyse the effect of univalents on recombination.

4.0 RESULTS

4.1 Recombination rate studies among durum (Kofa/W9262-260D3) chromosomes

4.1.1 Recombination along the length of each durum (Kofa/W9262-260D3) chromosome

For this analysis a linkage map was developed for the (Kofa/W9262-260D3) and was similar to that developed by Nilsen *et al.* (2017) who used the same population. Both ‘Kofa’ and ‘W9262-260D3’ are elite durum wheat lines. A total of 4,227 SNP markers were polymorphic between parents and the map spanned a total of 2,282 cM (Appendix A) (Nilsen *et al.*, 2017). In the present study, we compared the recombination rates along all chromosomes (Fig. 4.1). There was variation in recombination over the length of all chromosomes. As expected, the centromeric regions had suppressed recombination whereas telomeric regions showed higher recombination as compared to peri-centromeric regions (Fig. 4.1). For all the chromosomes, the linkage groups with high marker density had small and long arm junctions which are likely associated with the centromeric region (marked with red lines on x-axis) (Fig. 4.1) whereas the chromosomes 1A, 1B, and 5B, only showed recombination in their long arms and therefore putative centromeric regions could not be identified (Fig. 4.1). The distribution of monomorphic markers (green color) can also be seen in the Fig. 4.1 and showed large regions of the genome that are identical by state. These were large in number which is normal. The large represents the region where there was missing data and no mapped markers. The distribution of markers is according to the presence of genes. According to wheat 90k SNP assay, the number of mapped SNP loci for A genome chromosomes was 16,662 and for B genome was 23411 (Wang *et al.*, 2014). The list of monomorphic markers can be seen in appendix F.

Differences in recombination profiles were observed between the short and long arms of the chromosomes. In comparison to long arms, in short arms the proportion of distal recombination was higher than that of proximal and interstitial recombination (with no or very low recombination). In long arms, recombination was absent in the regions adjacent to

centromere and was mainly concentrated in the distal regions with less recombination in the interstitial regions. For example, in chromosome 1A, 1B, and 5A, the long arm showed maximum recombination in the telomeric and peri-centromeric regions of the chromosomes and in chromosome 2A, 3A, and 4B, the short arms can be seen with maximum recombination in the telomeric regions only with no recombination in peri-centromeric regions (Fig. 4.1). Hence, 25-30 % of total recombination occurred in the distal regions of chromosome. The regions with high recombination rates can be termed as recombination hotspots. On the other hand, the regions devoid of recombination are the coldspots.

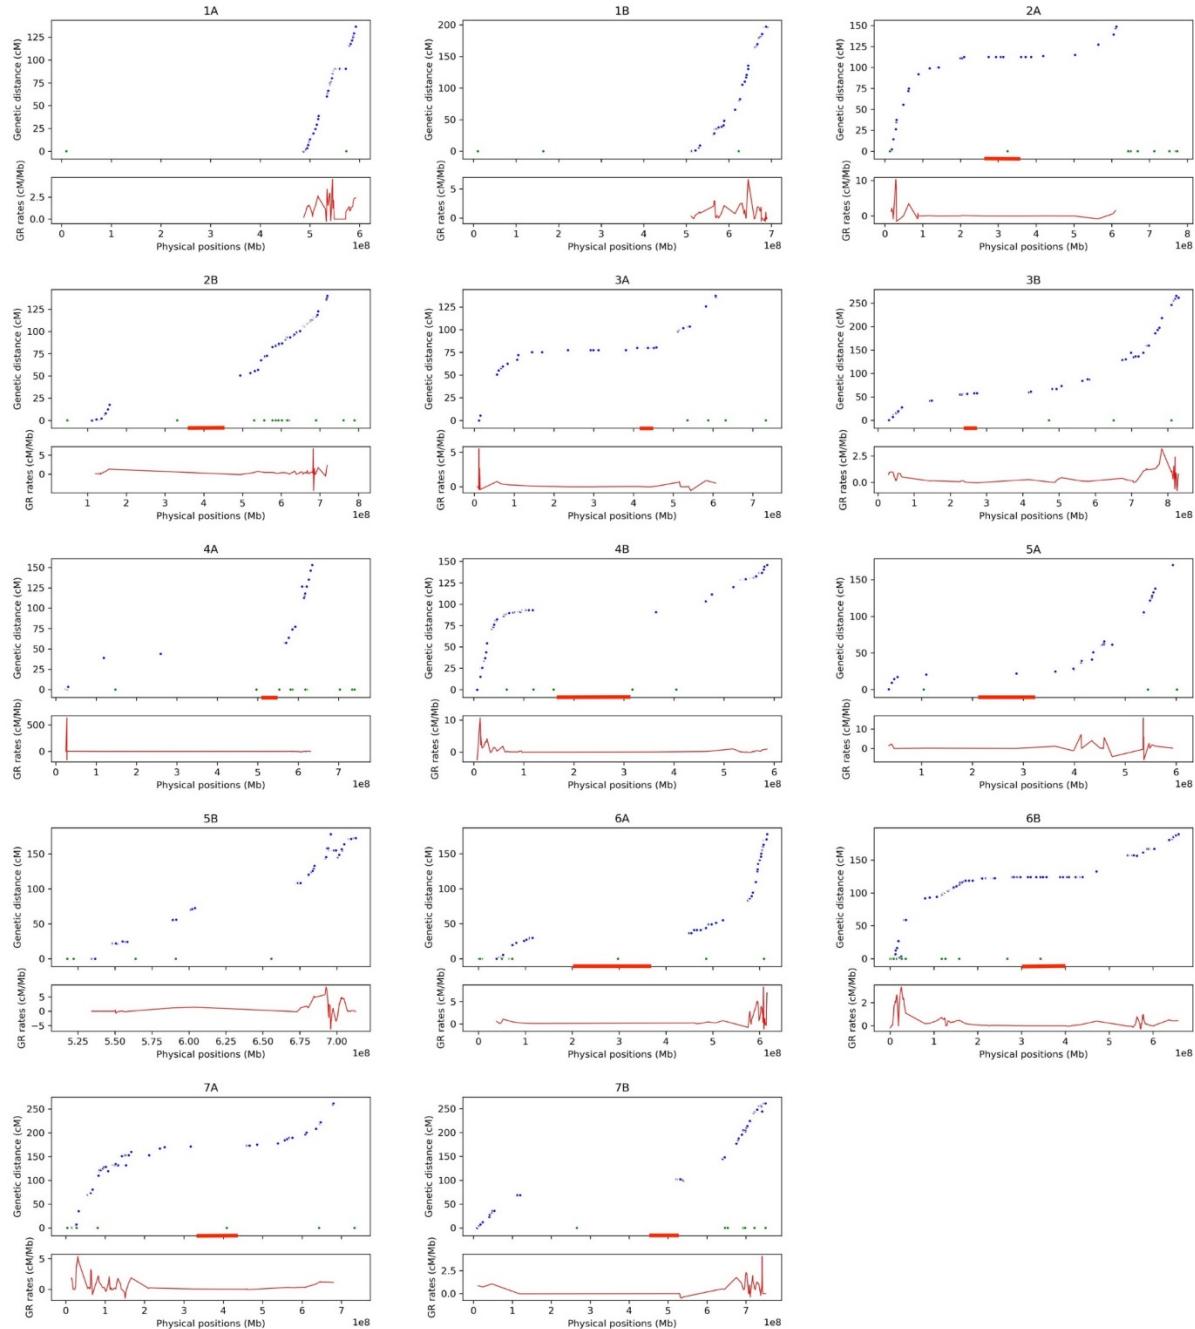

Fig 4.1. Graphic representation of the correlation of genetic and physical maps, the estimated local recombination rates along with their distribution over chromosomal regions. In scatter plots, the blue dots represent the genetic and physical positions of markers. The red curves on x-axes represent the estimated local recombination rates. The red mark on x-axes depicts the estimated centromere position based on consensus maps. The green dots represent the monomorphic markers distributed in each chromosome.

Table 4.1. Least square means' comparisons for recombination rates in 'Kofa/W9262-260D3'. According to Fisher's least significant difference (LSD), means followed by the same letter are not statistically significantly different at $P= 0.05$. The rates were recorded in cM/Mb.

Chromosome	Mean	Standard error	Max. recombination rate
		of mean	
6A	1.33 a	0.09	8.18
5B	1.22 ab	0.08	8.45
4A	1.10 a-d	0.17	6.72
1A	1.07 bc	0.08	4.48
5A	0.97 b-e	0.15	15.81
4B	0.88 cde	0.08	10.64
1B	0.86 cde	0.09	6.57
2A	0.85 c-g	0.16	10.31
2B	0.77 def	0.08	6.67
7B	0.66 efg	0.08	4.09
3B	0.56 fgh	0.08	3.20
7A	0.54 gh	0.08	5.40
6B	0.40 hi	0.06	3.35
3A	0.29 i	0.09	5.51

4.1.2 Comparisons of the mean and maximum recombination rates among all chromosomes

In both A and B genomes, high mean recombination rates were observed for 6A (1.33 cM/Mb), 5B (1.22 cM/Mb), 4A (1.10 cM/Mb), and 1A (1.07 cM/Mb) chromosomes (Table 4.1). The mean recombination rates for these chromosomes were not statistically significantly different from each other. There were significant differences between chromosomes 6A, 5B, 4A, and 1A (mean of approximately 1 cM/Mb) and the chromosomes 7A, 6B, and 3A (mean equal to or less than 0.5 cM/Mb). The maximum recombination rate was observed on chromosome 5A (15.81 cM/Mb) followed by 4B (10.64 cM/Mb) and 2A (10.31 cM/Mb) whereas the lowest maximum recombination rate was on chromosome 1A (4.48 cM/Mb) (Table 4.1). For all the chromosomes,

the minimum recombination rate recorded was 0 cM/Mb which indicated no recombination or there was at least one individual RIL in the population for which at least one chromosome was of parental type. On average, the A genome (0.83 cM/Mb) showed higher recombination than the B genome (0.73 cM/Mb) (Table 4.2). The mean recombination rate for chromosomes 1A, and 6A was higher and significantly different from their homoeologous chromosomes 1B, and 6B, respectively. Whereas the mean recombination rate for 2A, 4A, 5A, and 7A was not significantly different from 2B, 4B, 5B, and 7B, respectively. Only chromosome 3B showed more recombination than its homoeologous chromosome 3A (Table 4.1).

Table 4.2 Least square means' comparisons for recombination rates in (Kofa/W9262-260D3) for A and B genome. According to Fisher's least significant difference (LSD), means followed by the same letter are not statistically significantly different at $P= 0.05$. The rates were recorded in cM/Mb.

Genome	Mean	Standard error of mean
A	0.83 a	0.04
B	0.73 b	0.03

4.2 Recombination rate studies in the presence of univalents for three populations (Langdon/W9262-260D3, W9262-260D3/Langdon triticale, and DGE-1/W9262-260D3)

4.2.1 F₁ seeds and their KASP analysis

The total number of F₁s harvested from the cross W9262-260D3/Langdon triticale was 25 (Fig. 4.2 (b)). The seeds were very shriveled and only 14 seeds germinated. The F₁ seeds harvested from the cross Langdon/W9262-260D3 were healthy and showed good germination (Fig. 4.2 (a)). The F₁ seeds from DGE-1/W9262-260D3 were a little shriveled (Fig. 4.2 (c)) but germinated well. The total number of seeds harvested from all the crosses are listed in Table 4.3.

Table 4.3. Total number of seeds per cross

Cross	Number of seeds
(Langdon/W9262-260D3)	>100
(W9262-260D3/Langdon triticale)	25
(DGE-1/W9262-260D3)	>100

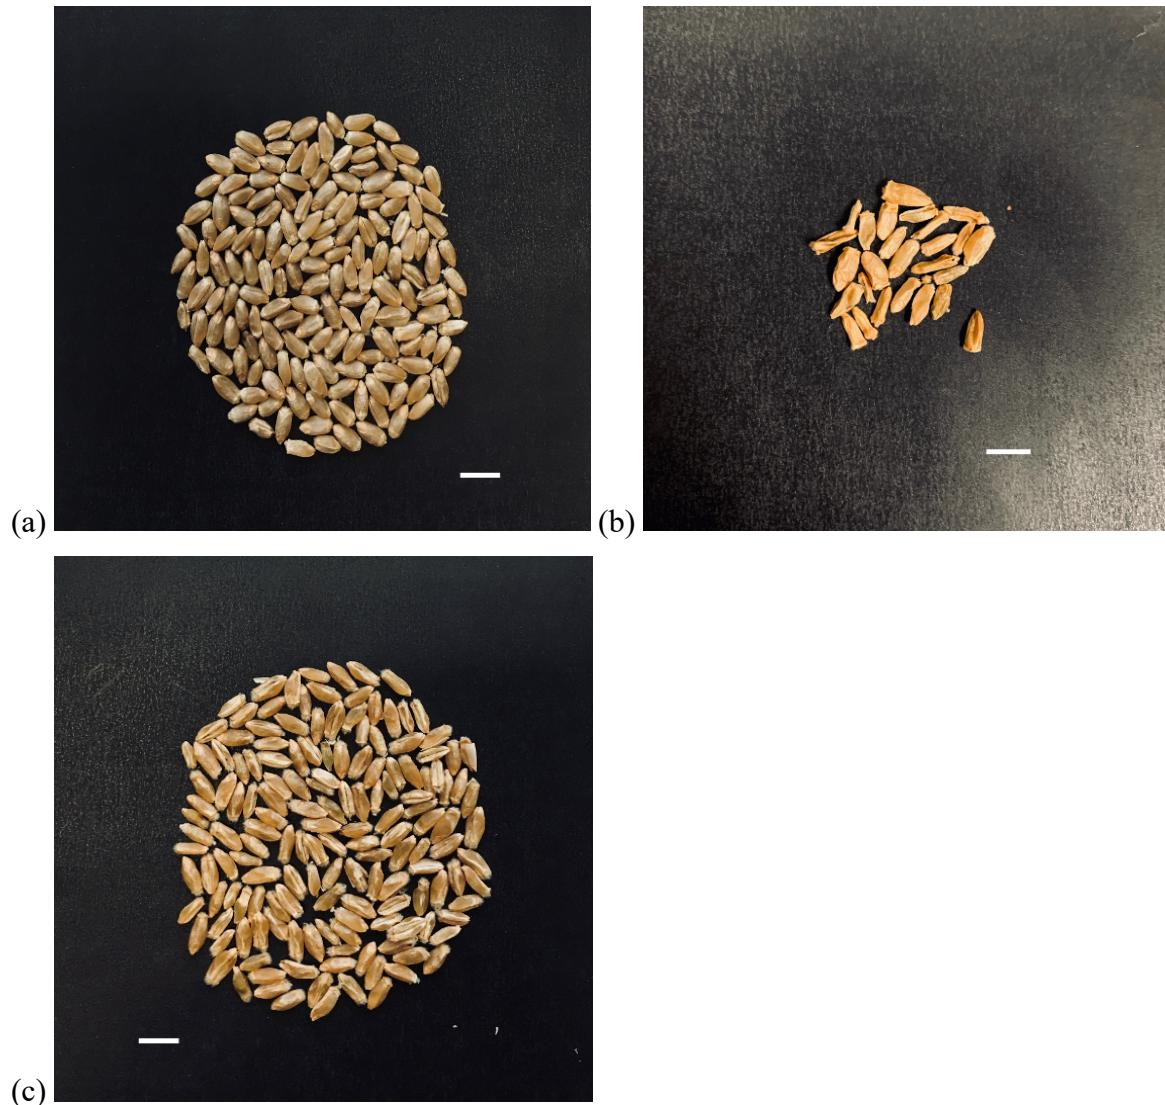

Fig. 4.2. F1 seed of (a) (Langdon/W9262-260D3) (b) (W9262-260D3/Langdon triticale), and (c) (DGE-1/W9262-260D3). The scale bar, representing 1cm, is highlighted with white line.

Seeds from the crosses, (W9262-260D3/Langdon triticale) and (DGE-1/W9262-260D3) were analyzed using KASP markers to check whether they were crosses or not. For the cross W9262-260D3/Langdon triticale, out of 14 seeds, 8 were found to be crosses (Fig. 4.3 (a)) and in the cross of wheat addition line DGE-1 with W9262-260D3, out of 32 seeds, 29 were crossed seeds with only 3 selfed ones (Fig. 4.3 (b)).

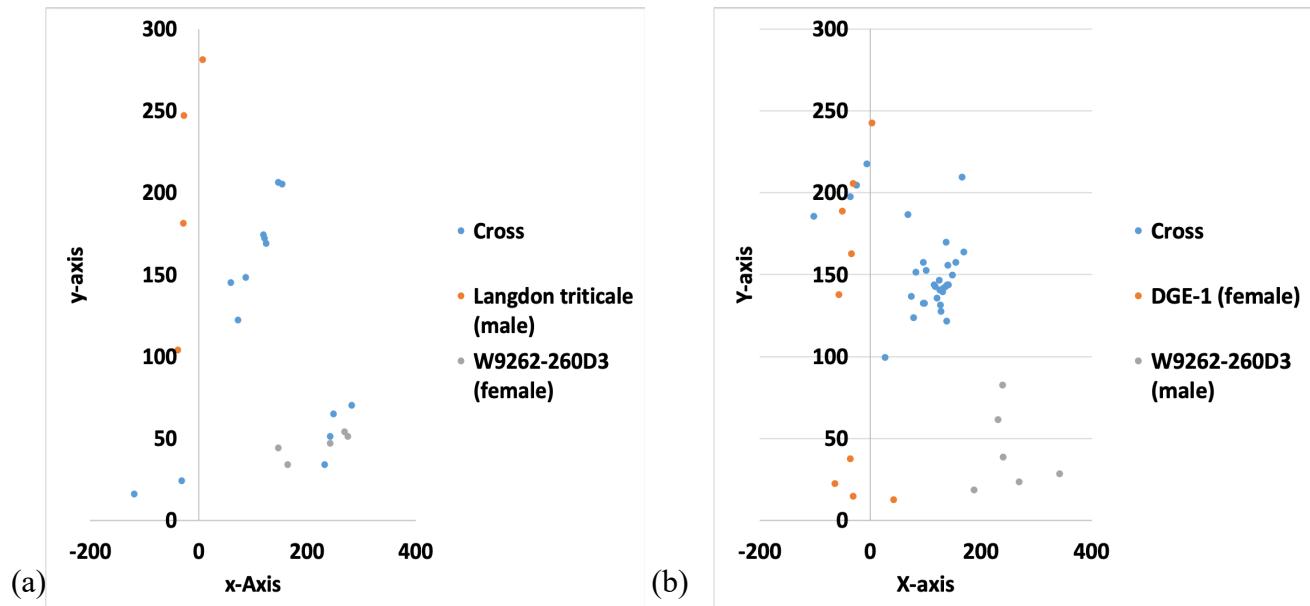

Fig. 4.3. KASP analysis plots using *Cdu1* markers showing a cluster plot with two genotyping parental clusters along with its heterozygous progenies. In these plots, x-axis is assigned as homozygous alleles for W9262-260D3 and y-axis as homozygous alleles for Langdon triticale and DGE-1 parents, respectively. (a) W9262-260D3/Langdon triticale (b) DGE-1/W9262-260D3

4.2.2 F₂ seeds and their data

All the F1 plants were grown and the number of seeds per spike were counted for each plant in all the three crosses (Langdon/W9262-260D3), (W9262-260D3/Langdon triticale) and (DGE-1/W9262-260D3). The number of seeds varied for each plant and many seeds were found to be shriveled. In first cross (Langdon/W9262-260D3), the plants were very healthy. The number of spikes and seed count per plant can be seen in Table 4.4.

Table 4.4. Data from cross (W9262-260D3/Langdon triticale)

F ₁ Plant No.	Number of spikes	Number of seeds
L-1	42	635
L-2	35	487
L-3	40	577
L-4	33	492
L-5	36	609

From the cross (W9262-260D3/Langdon triticale), the plant P-9 had the maximum number of seeds including the shriveled seeds (Fig. 4.4). DNA was extracted from more than 200 seedlings. The seed count for all plants is shown in Table 4.5. The smallest number of seeds were found in P-7 and all of those were very shriveled (Fig. 4.4).

Table 4.5 Data from cross (W9262-260D3/ Langdon triticale)

F ₁ Plant No.	Number of spikes	Number of seeds
P-1	17	250
P-4	21	165
P-6	19	420
P-7	12	26
P-9	33	655
P-11	16	375
P-13	15	163
P-14	15	585

Fig. 4.4. F₂ seeds from cross (W9262-260D3/Langdon triticale): (a) P-6 (b) P-7 (c) P-9 (d) P-11. The scale bar, representing 1cm, is highlighted with a white line.

In the cross with wheat addition line (DGE-1/W9262-260D3), a few plants were kept, and seed count was done. From F₂ population, plant D-19, DNA was extracted from 180 young leaf samples. Some of the seeds were shriveled (Fig. 4.5) and the number of seeds per plant was different (Table 4.6). From the plants D-2, D-6, and D-15, the number of seeds per plant were fewer than 100 because of spike sterility and shriveled seeds (Table 4.5).

Table 4.6. Data from Cross (DGE-1/W9262-260D3)

Plant No.	Number of spikes	Number of seeds
D-2	15	81
D-6	18	87
D-12	19	191
D-15	15	72
D-16	18	274
D-19	12	350
D-20	26	162

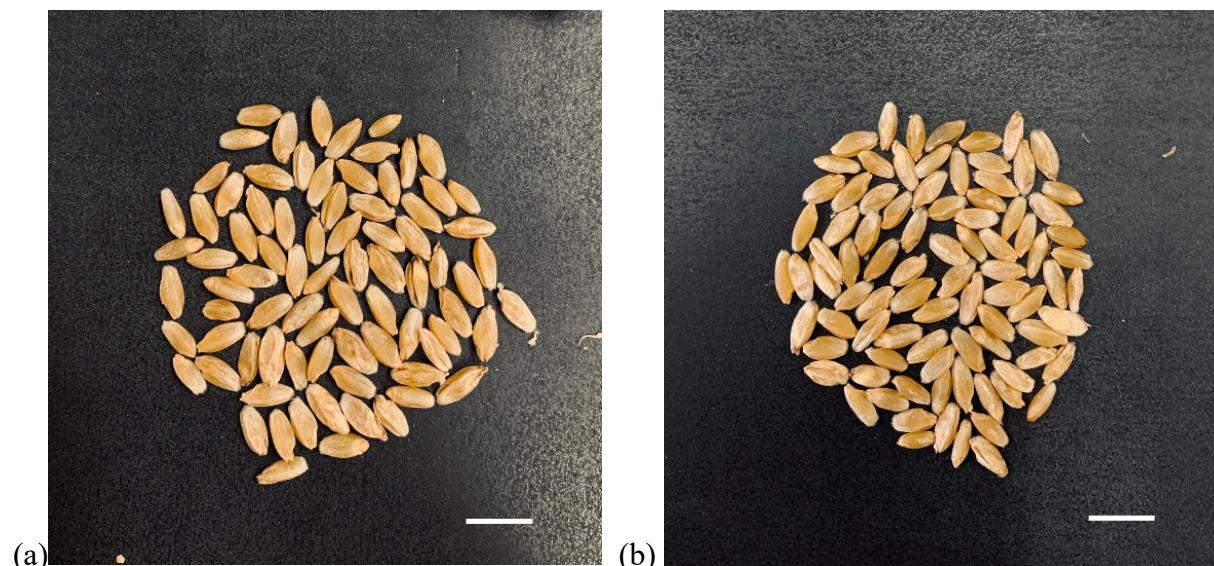

Fig. 4.5. F₂ seeds from cross (DGE-1/W9262-260D3): (a) D-2 (b) D-6 (c) D-15 (d) D-16. The scale bar, representing 1cm, is highlighted with a white line.

4.2.3 Comparative analysis in recombination rates in three populations

A total of three populations i.e. Pop1 (Langdon/W9262-260D3), Pop2 (W9262-260D3/Langdon Triticale), and Pop3 (DGE-1/W9262-260D3) comprising 190, 212, and 172 recombinant lines, respectively, were genotyped using the wheat Illumina 90K iSelect SNP assay (consisting of 81,687 SNPs) (Wang *et al.* 2014). Using the Chi-square statistic, a total of 2825, 1857, and 3110 polymorphic markers, showing expected segregation of either 1:2:1, 1:3, or 3:1 ratio were extracted from Pop1, Pop2, and Pop3, respectively. The difference in the number of polymorphic SNP markers per chromosomes is shown in Fig. 4.6. For each chromosome of all populations, approximately 1-4 linkage groups were found, and for instance, if chromosome 1A has three linkage groups then it can be written as 1A-1, 1A-2 and 1A-3 (Table 4.7). The data regarding genetic mapping as number of linkage groups, number of markers, length and largest interval group is shown in Table 4.7. The genetic maps of all these populations can be seen in Appendix B, C, and D.

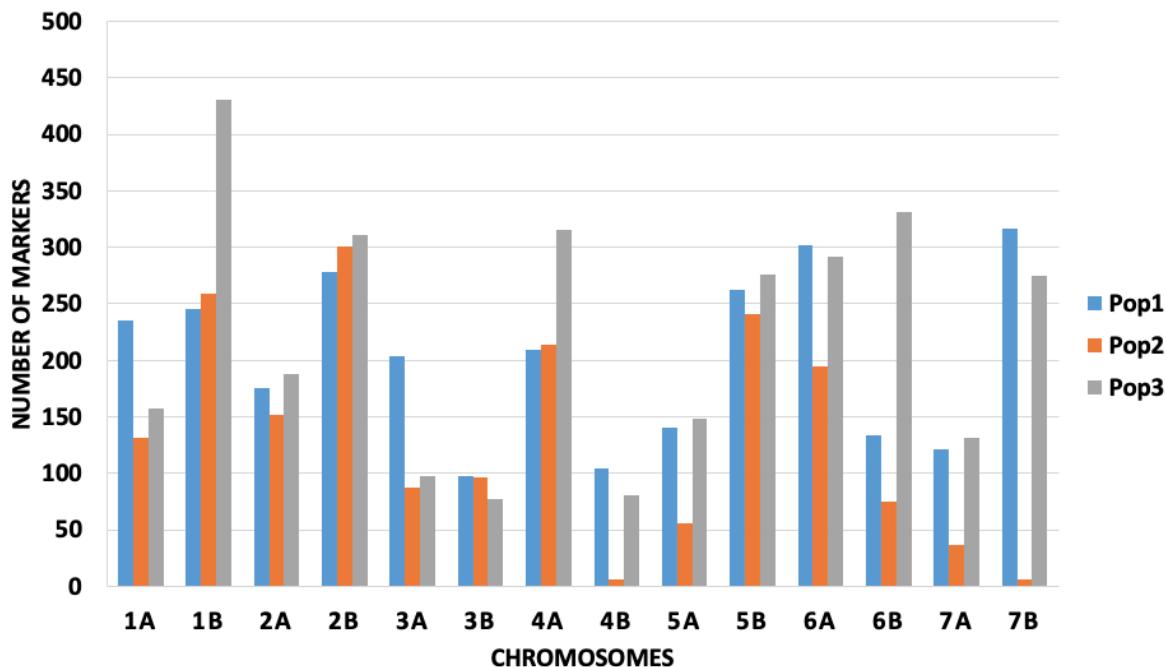

Fig. 4.6. Difference in the number of polymorphic single nucleotide polymorphism (SNP) markers per chromosome for each population.

Table 4.7. Descriptive statistics of genetic maps of three populations.

Pop1 (Langdon/W9262-260D3)

4.2.4. Comparison of genome-wide recombination rates

The recombination rates were estimated for each chromosome using the genetic and physical positions of the SNP markers (Gion *et al.*, 2016). The genome-wide recombination rates varied significantly along the length of each chromosome in all the populations. The least square means comparisons were calculated for all three populations for each chromosome. Higher recombination rates were observed at distal ends than the proximal chromosomal regions in all the populations. The recombination rate was maximum in Pop2, followed by Pop3, and least in Pop1 at certain regions in each chromosome. The minimum recombination rate recorded was 0 cM/Mb in all the populations whereas the highest varied among all (Table 4.8). For instance, in chromosome 2B, the highest mean recombination rate was found in Pop3 (0.48 cM/Mb), followed by Pop2 (0.34 cM/Mb), and least in Pop1 (0.24 cM/Mb). The maximum recombination

rate for Pop1, Pop2, and Pop3 was recorded as 0.73, 0.96, and 1.08 cM/Mb, respectively (Table 4.8). Also, in chromosome 3A, Pop2 (0.48 cM/Mb) showed high mean of recombination than Pop1 (0.29 cM/Mb) and Pop3 (0.15 cM/Mb). There was no significance difference found in means of Pop1 and Pop3. The maximum recombination rate was recorded in Pop2 as 4.62 cM/Mb (Table 4.8).

Table 4.8. Least square means' comparisons for recombination rates in the three populations. Means followed by the same letter are not statistically significantly different according to Fisher's least significant difference (LSD) at $P = 0.05$.

Chromosome	Population	Mean	Standard	Max.

4.3 Overall comparison of recombination rates of three populations with (Kofa/W9262-260D3) population

The comparison among the populations showed that the presence of alien chromatin was responsible not only for the increased recombination in some chromosomes but also suppressed recombination in others. The differences in recombination were seen in Pop2 and Pop3 in comparison to Pop1 and Kofa/W9262-260D3 population. For instance, in the short arm of chromosome 1A, the maximum recombination rate was recorded in Pop2 (peak value 6.92

cM/Mb), and Pop3 (peak value 4.40 cM/Mb) whereas in the long arm, Pop3 showed more recombination in the telomeric region (peak value 7.61 cM/Mb) than Kofa/W9262-260D3 (peak value 4.48 cM/Mb) (Table 5.1). In chromosomes 1B, 2A, and 2B, the recombination was maximum in Pop2 and Pop3 with increased recombination hotspot regions in the peri-centromeric regions along with telomeric regions. For chromosome 3A, again Pop2 was found to have increased recombination hotspot region in the long arm with a maximum recombination rate of 4.62 cM/Mb and Pop3 also showed recombination hotspots in peri-centromeric regions (Table 5.1). Although, Pop2 and Pop3 were identified to have recombination coldspots in some parts of the chromosomes, recombination was seen to cover the peri-centromeric regions as well as telomeric regions of the chromosomes. Hence, overall recombination was found to be changed across the length of some chromosomes in the presence of alien chromatin.

Table 5.1 Comparison of recombination among all populations: Kofa/W9262-260D3, Pop1 (Langdon/W9262-260D3), Pop2 (W9262-260D3/Langdon triticale, Pop3 (DGE-1/W9262-260D3). The recombination region is described using start and end of physical position on particular arm of each chromosome for each population. The peak recombination value (cM/Mb) is depicted to show the maximum recombination happening in the region.

Chromosome	Population	Physical position (Mb)					
		Short arm			Long arm		
		Start	End	Peak recombination value (cM/Mb)	Start	End	Peak recombination value (cM/Mb)

5.0 DISCUSSION

5.1 Intercrossing of species differing in ploidy levels.

The crossing between triticale and wheat is a common practice for improving essential traits and diversity in wheat breeding. Major concerns in crossings include the reduced fertility of hybrids and shriveled kernels. For this thesis, three populations were developed from three crosses. The first cross between the durum wheat parents, Langdon and W9262-260D3 produced good seeds. The F₁s harvested from this cross were healthy and showed good germination. The cross between Langdon triticale and W9262-260D3 (when Langdon triticale was used a female) produced a very low seed set (~10 seeds). The seeds were very shriveled and found to be the result of selfing. In the reciprocal cross, when triticale was used as a male, there was good seed set but again the seeds were shriveled. Out of a total of 25 seeds harvested from this cross, only 14 seeds were able to germinate. This is possibly due to chromosomal imbalance as in previous studies it was found that poor pollen germination, retardation and inhibition of the growth of the pollen tubes in the pistils at the base of the style were found to be the main reasons for poor crossability in triticale and wheat crosses. The seed developed from these crosses is always shriveled (Singh and Khanna, 1983). Scott et al. (1998) also found that seeds developed from crosses between individuals with different ploidy levels were abnormal and usually abort. The factor, responsible for this, was the contribution of more chromosome sets by the mother or father which might be because of their functional inequivalence. In *Arabidopsis thaliana*, a cross between diploid and tetraploid plant, inhibition of endosperm development causing a smaller embryo development was seen when the double dose of maternal genome was there as compared to paternal genome. On the other hand, the double dose of paternal genome promoted the growth of endosperm and embryo. Hence, different doses of maternal or paternal genomes could be another factor responsible for the imbalance in the endosperm development and ultimately the abortion of seeds (Scott et al., 1998). A study was performed by Lukaszewski and coworkers (1982) to check the transmission of chromosomes through egg and pollen of crossed F₁ hybrids (Triticale and Hexaploid wheat). It was found that the seed set from (triticale X wheat) crosses was about 50% and all the seed from the reciprocal cross was inviable due to endosperm imbalance (Lukaszewski *et al.*, 1982). In the addition line x wheat cross, DGE-1 was used as the female and it gave very good seed set. The F₁ seeds were very thin but showed good

germination. This addition line, DGE-1, was meiotically and reproductively stable, generally forms 15 bivalents and was the source of single univalents (Jauhar *et al.*, 2009). The F₁s, from all the crosses, were sown in the petri-plates and were kept at 4°C for three days and then transferred to pots to keep under normal growth conditions. The F₁s from Langdon/W9262-260D3, yielded a good number of F₂ seeds. On the other hand, F₂ seed from the other two crosses varied in number for every plant and were very shriveled, again due to meiotic irregularity and partial sterility. Also, in *Arabidopsis thaliana*, Duszynka *et al.* (2019) found that cross between diploid and tetraploid plants can be able to produce viable F₁ triploid plants. On selfing, these F₁ triploids produce aneuploids with potential to cause F₂ seed abortion. This is probably due to the strong interaction between the two factors as the presence of natural variation and cross direction (Duszynka *et al.*, 2019).

5.2 Genetic mapping and recombination

Genetic maps show the position of the markers on the chromosome along with the genetic distances between them. In the construction of genetic maps, map lengths and marker orders are affected by the type and size of populations, type of markers (dominant or codominant), genotyping errors, segregation distortion, frequency of double recombinants, and statistical procedures used (Hackett and Broadfoot, 2003; Ferreira *et al.*, 2006; Zuo *et al.*, 2019). The precision of the genetic maps increases with the increase in the number of individuals and 200 individuals in total can be sufficient for the construction of accurate genetic maps (Ferreira *et al.*, 2006). In segregation distortion, the distorted markers can have positive impacts on the construction of genetic maps as they can significantly change the grouping markers on their corresponding chromosomes and also increase the linkage map consistency with genome coverage (Zuo *et al.*, 2019). In this thesis, as per the hypothesis, there was no linkage study and hence, these were not included. It is not affecting the expected results. Also, In a study of segregation distortion in soybean by Zuo *et al.* (2019), it was found that the exclusion of the significantly distorted markers will result in decrease of the total genetic distance and marker density but increase the average marker-distance on the chromosomes. In this thesis, the comparisons between DH population and F₂ populations were made. DH population are completely homozygous because of the presence of only one allele for each gene. Whereas the F₂ populations are the ones with maximum genetic variation. Also, before becoming fixed, DH

populations go through only one round of recombination whereas other population types generally go through many rounds of recombination. Hence, on the basis of DH population, the recombination was compared with all populations. The DH haploid map used in this study was a high-density genetic map and was more helpful in correct idea about the recombination.

5.2.1 Recombination rates within durum chromosomes

Recombination is an important characteristic to study in order to exploit the genetic diversity for plant breeding. Durum is an allotetraploid wheat (*Triticum turgidum* L., $2n=4x=28$) with 2 sets of chromosomes, its chromosomal complement has the A genome, derived from *T. urartu* Thum. ($2n=2x=14$, AA genome), and the B genome from an undiscovered or extinct species related to *Aegilops speltoides* Tausch ($2n=2x=14$, SS/BB genome) (Dvorak and Zhang, 1990; Dvorak *et al.*, 1993). In wheat, previous studies also revealed that the telomeric regions were found to be the highly recombinogenic whereas the peri-centromeric regions had less or no recombination (Erayman *et al.*, 2004; Saintenac *et al.*, 2009). COs are not uniformly located along the length of chromosomes as the presence of euchromatin and heterochromatin along the chromosome is linked with CO formation and euchromatin regions, being enriched in genes and under active transcription, are more prone to CO formation in telomeric regions (Naranjo, 2015; Higgins *et al.*, 2014).

The recombination rates were estimated and compared to determine the effects of alien chromatin on recombination rates of native wheat chromosomes. The maximum recombination was recorded in chromosomes 5A, 6B, 6A, 4A, and 1B. The maximum recombination rate measured for these chromosomes was more than 5 cM/Mb. The recombination varied along the length of each chromosome. In physically short arms, the recombination was seen in the telomeric regions only. Whereas in physically long arms, the recombination was found to be high in telomeric regions and less or no in peri-centromeric regions. In chromosomes 2A, 3A, 4B, 6B, and 7A, there was high recombination in the telomeric regions of the short arms as compared to chromosomes 2B, 3B, 5A, 6A, and 7B, where the long arms showed maximum recombination in the telomeric regions. In chromosome 1AL and 1BL, the variation in recombination was found along the whole length. Recombination was higher in sub-telomeric regions than extreme telomeric regions. The peak recombination rates were found in chromosome 1A (4.48 cM/Mb) and chromosome 1B (6.57 cM/Mb) (Fig. 4.1). In chromosomes like 2A, 3A, 4B, 6B and 7A, the recombination was high in telomeric region of the small arm. The recombination was uniformly

low towards centromere and showed a little recombination in the telomeric region of long arm. Whereas in chromosomes 2B, 3B, 5A, 6A, and 7B, the recombination was less in telomeric region of small arm and there was no recombination in centromeric regions. The increase in recombination was found from peri-centromeric position to telomeric position in long arm. Typically, in chromosome 4A, the high recombination was found in telomeric regions of both small and long arm. The maximum recombination rate in small arm was 6.72 cM/Mb whereas in the long arm, it was 5.77 cM/Mb (Fig. 4.1).

Many genes are responsible for controlling the recombination in wheat. *Ph1* locus on chromosome 5B is responsible for controlling the homoeologous pairing between the chromosomes A and B genome chromosomes while chromosomes of these diploid species do show pairing in hybrids (Riley and Chapman, 1958; Sears, 1976; Al-Kaff *et al.*, 2008; Griffiths *et al.*, 2006). Recently, the *Su1-Ph1* locus, found on the distal (high recombination region) of the long arm of the *Aeilops speltoides* chromosome 3S, was introgressed into wheat to suppress activity of *Ph1* locus in order to induce homoeologous recombination (Li *et al.*, 2019). In chromosome 4A and all other chromosomes in the B genome, the peri-centromeric regions are highly rich in heterochromatin and hence there is inhibition in CO formation (Gaut *et al.*, 2007). In chromosome 3BS, the high heterochromatin content found in telomeric region which results in reduced recombination (Saintenac *et al.*, 2009). Particularly in the B genome, the proximal halves appear to be fully capable of meiotic pairing as well as chiasma formation and still do not show recombination. It depends on the time span of chromosome pairing as at or near telomeric regions as the primary initiation of synaptonemal complex take longer time period over there (Holm, 1986). Akhunov and coworkers found that the recombination rate and wheat genome organization with evolution are related to each other as duplication derived loci concentrated preferentially in high recombinogenic distal regions whereas the ancestral copies accumulated in low recombinogenic proximal regions (Akhunov *et al.*, 2003).

5.2.2 Variation in recombination rates among populations that had univalents during F₁ meiosis

In this study, the recombination rates were estimated which depends on the genetic distance and physical position of the markers and outliers were removed, as they were falling out of the graphs and the software gave no reading for those, from the graphs to calculate the

recombination rates. In genetic mapping, Pop3 had the highest number of polymorphic markers and hence, the maps were dense with fewer gaps, followed by Pop1 and then Pop2. In Pop2, there were only 1857 polymorphic markers. The parental source of Langdon and W9262-260D3 was different. There may be heterogeneity among the parents and also the population size was different in all the crosses. However, all the chromosomes had enough markers to calculate and compare recombination rates except chromosome 4B and 7B. The linkage groups were fragmented due to a smaller number of markers, and wherever the genetic distance between the markers exceeded 30 cM, a different linkage group was formed. However, this did not affect the measurement of recombination. In this study, results showed that the presence of alien chromatin gave rise to increased recombination rates in Pop2 and Pop3 in some chromosomes at some points as expected. In chromosome 1B, 2A, 2B, and 3B, the recombination rates were found to be higher in Pop3 and Pop2 than Pop1. In Pop2, rye univalents at meiosis were responsible for increasing the overall recombination in chromosome 3A, 3B, 6B, and 7A. Also, in comparing the recombination rates on the basis of position on chromosome, there were high recombination in the telomeric regions as compared to the peri-centromeric and centromeric regions. On chromosomes 1B, 2B, 3A, 4A, and 6B, the recombination rates were high for both telomeric and peri-centromeric regions in both Pop2 and Pop3 as compared to Pop1, while on chromosome 1A, 1B, 2A, 2B, 3A, 3B, 6A, 6B, and 7A, Pop3 and Pop2 showed very high recombination at some points in the telomeric regions. Suppression of recombination was also seen at some points on the chromosomes, for instance, on chromosome 3A, 4B, 5A, and 7B, Pop3 showed less recombination as compared to Pop1. Similarly, Pop2 also showed suppressed recombination at some points (including telomeric regions) on chromosome 2A, 2B, 3A, 5B, and 6A.

It was found that the suppression of recombination and CO formation in proximal regions of wheat chromosomes is a common feature (Erayman *et al.*, 2004; Saintenac *et al.*, 2009). Heterochromatin and euchromatin distribution along telomere-centromere axis has a link with CO formation and recombination as the presence of heterochromatin is responsible for the inhibition of CO formation and hence takes part in suppressing the recombination in proximal regions of the chromosome (Higgins *et al.*, 2014; Guat *et al.*, 2007). Univalents are known to trigger meiotic recombination as they cause the nucleus to linger in active recombination state and hence influence the remaining chromosomes which synapsed correctly changing their CO number and distribution (Suay *et al.*, 2014; Martinez-Perez & Moore, 2008). Hence, we can say

that recombination highly varied across the length of chromosomes for all the populations. It is possible that univalents can cause change in meiosis leading to alter the CO distribution and frequency.

6.0 CONCLUSIONS AND FUTURE WORK

Durum wheat is a species of great importance just like common wheat, well adapted to more extreme environmental conditions and from a very long time, researchers are working to incorporate desirable traits into elite germplasm (Bozzini, 1988). The allopolyploid genome of wheat is able to tolerate various modifications in structure, chromosomal addition, and elimination without influencing general characteristics and fertility (Silkova *et al.*, 2013). The current scenario to improve wheat is based on the combination of innovative approaches and breeding strategies like mixing of germplasm through crossing, biotechnological techniques, interspecific and intergeneric hybridization, and physiological studies (Reif *et al.*, 2005). However, recombination plays an important role in domestication, genomic evolution and crop improvement. The recombination studies revealed that ploidy level crosses can help in achieving recombination along the entire length of chromosomes. Presence of alien chromatin affects the overall recombination of chromosomes and hence giving more chances to peri-centromeric regions to recombine. In this study, Pop2 and Pop3 were found to cover the peri-centromeric regions as well as telomeric regions more than normal wheat chromosome recombination. In both populations, the recombination rates were also high and suppressed at some points of chromosomal recombination. In future, directed modulation of recombination frequency can be helpful in improving the efficiency of plant breeding programs by expediting attainment of desired combinations of alleles. The disruption of genetic barriers is an important key to enable genetic accessibility of natural variation as well as introgression of desired traits from related or wild species into crops. The work done in this research will utilize existing genetic stocks which are available to the CDC in achieving the genetic gain which can be used in long-term genomic selection programs where its effects can be seen more clearly after four to five generations and can retain genetic diversity for a longer period of time.

Appendix E. Graphical representation of the correlation of genetic and physical maps, the estimated local recombination rates along with their distribution in chromosomal rearrangement regions. In scatter plots, the red dots represent the genetic and physical positions of markers. The red curves below the plots represent the estimated local recombination rates. The dark green color dots represent the distribution of monomorphic markers. (a) Pop1 (Langdon/W9262-260D3). (b) Pop2 (W9262-260D3/Langdon triticale). (c) Pop3 (DGE-1/W9262-260D3)

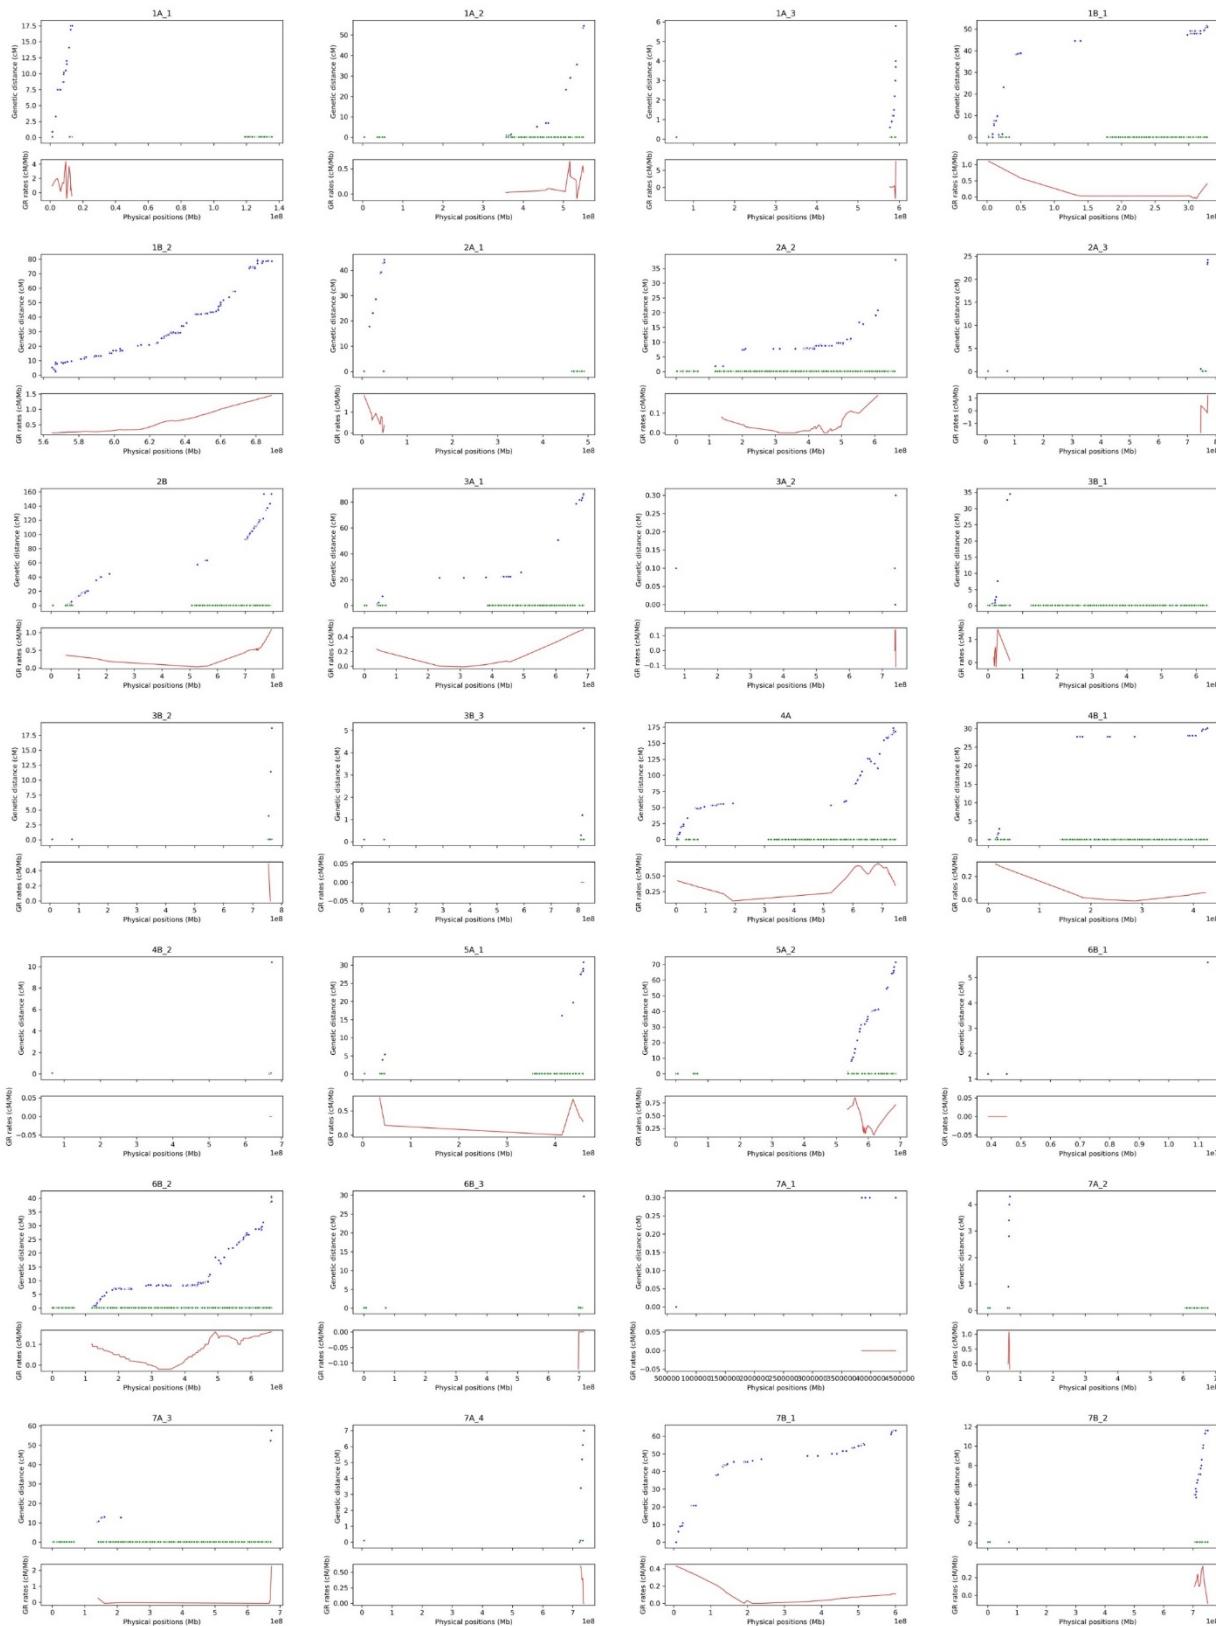

(a) Pop1 (Langdon/W9262-260D3)

(b) Pop2 (W9262-260D3/ Langdon triticale)

(c) Pop3 (DGE-1/W9262-260D3)

Appendix F. List of monomorphic markers for population Kofa/W9262-260D3
